H Temperleri

TABLE 13-4 ■ *Temper designations for aluminum alloys*

| | |
|---|---|
| F | As-fabricated (hot-worked, forged, cast, etc.) |
| O | Annealed (in the softest possible condition) |
| H | Cold-worked |
| | H1x—cold-worked only. (x refers to the amount of cold work and strengthening.) |
| | H12—cold work that gives a tensile strength midway between the O and H14 tempers. |
| | H14—cold work that gives a tensile strength midway between the O and H18 tempers. |
| | H16—cold work that gives a tensile strength midway between the H14 and H18 tempers. |
| | H18—cold work that gives about 75% reduction. |
| | H19—cold work that gives a tensile strength greater than 2000 psi of that obtained by the H18 temper. |
| | H2x—cold-worked and partly annealed. |
| | H3x—cold-worked and stabilized at a low temperature to prevent age hardening of the structure. |
| W | Solution-treated |
| T | Age-hardened |
| | T1—cooled from the fabrication temperature and naturally aged. |
| | T2—cooled from the fabrication temperature, cold-worked, and naturally aged. |
| | T3—solution-treated, cold-worked, and naturally aged. |
| | T4—solution-treated and naturally aged. |
| | T5—cooled from the fabrication temperature and artificially aged. |
| | T6—solution-treated and artificially aged. |
| | T7—solution-treated and stabilized by overaging. |
| | T8—solution-treated, cold-worked, and artificially aged. |
| | T9—solution-treated, artificially aged, and cold-worked. |
| | T10—cooled from the fabrication temperature, cold-worked, and artificially aged. |

The letter *H* indicates:

strain hardened, cold-worked, hand-drawn, or rolled. Additional digits are added to the *H* to indicate the degree of strain hardening.

This letter designates a process of stretching or compressing in order to impart a particular temper.

H_1 1/8 hard

H_2 1/4 hard

H_3 3/8 hard

H_4 1/2 hard

H_5 5/8 hard

H_6 3/4 hard

H_7 7/8 hard

H_8 Full hard

- Isıl işleme cevap veren alaşımlara uygulanır
- T temper durumu

Heat Treatable Alloys Temper Designations

| Designation | Description | Application |
|--------------------|-------------------------------------|---|
| O | Annealed, Recrystallized | Lowest Strength, High ductility |
| F | As Fabricated | Fabrication with no special control over thermal or strain hardening |
| W | Solution Heat Treatment | Unstable temper application with subsequent period of natural age |
| T1 | | Cooled and naturally aged |
| T2 | | Cooled, cold worked & Naturally aged |
| T3 | | Solution heat treated, cold worked & naturally aged |
| T4 | | Solution heat treated & naturally aged |
| T5 | | Cooled and artificially aged |
| T6 | | Solution heat treated and Stabilized |
| T7 | | Solution heat treated, stabilized to provide special property |
| T8 | | Solution heat treated, cold worked, artificially aged |
| T9 | | Solution heat treated, artificially aged, then cold worked |
| T10 | | Cooled, cold worked, then artificially aged |

For a more extensive description see the table in AWS Welding Handbook, Vol 3, 8th Ed. Page 9

Heat treatment strategies

There are a number of **heat treatment strategies**, which stimulate the formation of dispersed precipitates that **resist cutting by dislocation**.

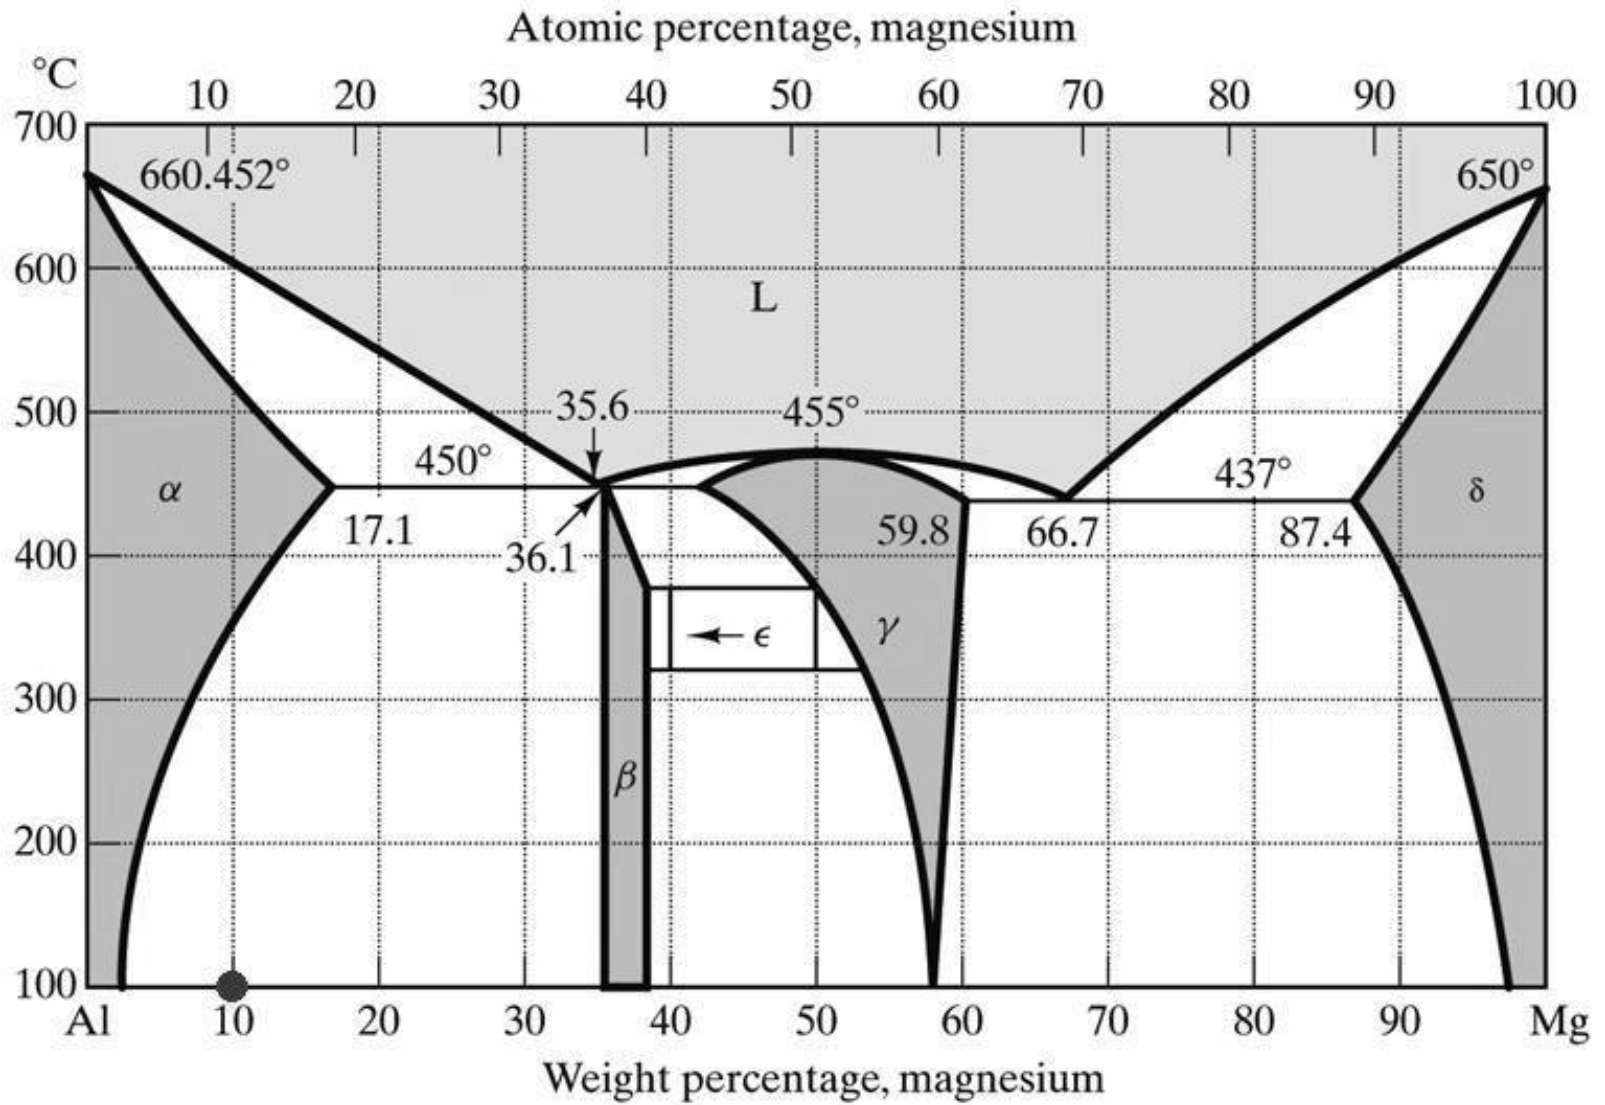

- 1) Duplex ageing first below and then above the GP zone solvus temperature, enabling the formation of finer dispersion of intermediate precipitates.
- 2) Co-precipitation of two phases, fine and coarse particles in which the former contributes to yield strength and the latter result in uniform plastic deformation.
- 3) Co-precipitation of two or more intermediate phases, having different crystallographic plane, influencing dislocation mobility.
- 4) Nucleation of uniform dispersions of intermediate precipitates by adding some particular trace elements.

Note: Suitable heat-treatment scheme can increase strength up to 40 times.

Alüminyum Malzemelerin Isıl İşlemleri ve Süreç Analizleri

Heat treating of aluminum and aluminum alloys

The general types of heat treatments applied to aluminum and its alloys are:

- **Preheating or homogenizing**, to reduce chemical segregation of cast structures and to improve their workability;
- **Annealing**, to soften strain-hardened (work-hardened) and heat treated alloy structures, to relieve stresses, and to stabilize properties and dimensions;
- **Solution heat treatments**, to effect solid solution of alloying constituents and improve mechanical properties;
- **Precipitation heat treatments**, to provide hardening by precipitation of constituents from solid solution

- Heat treating processes for aluminum are **precision processes**.
- They must be carried out in furnaces properly designed and built to provide the thermal conditions required, and adequately equipped with control instruments to insure the desired continuity and uniformity of temperature-time cycles.
- To insure the final desired characteristics, process details must be established and controlled carefully for each type of product.

INGOT PREHEATING TREATMENTS (HOMOGENIZING)

The initial thermal operation **applied to ingots prior to hot working is referred to as "ingot preheating"**, which has one or more purposes depending upon the alloy, product, and fabricating process involved.

One of the principal objectives **is improved workability**. **The microstructure of most alloys in the as-cast condition is quite heterogeneous**. This is true for alloys that form solid solutions under equilibrium conditions, and even for relatively dilute alloys

ANNEALING

- The distorted, dislocated structure resulting from cold working of aluminum is less stable than the strain-free, annealed state, to which it tends to revert. Lower-purity aluminum and commercial aluminum alloys undergo these structural changes only with annealing at elevated temperatures. Accompanying the structural reversion are changes in the various properties affected by cold working. These changes occur in several stages, according to temperature or time, and have led to the concept of different annealing mechanisms or processes.
- **Recovery.** The reduction in the number of dislocations is greatest at the center of the grain fragments, producing a subgrain structure with networks or groups of dislocations at the subgrain boundaries. With increasing time and temperature of heating, polygonization becomes more nearly perfect and the subgrain size gradually increases. In this stage, many of the subgrains appear to have boundaries that are free of dislocation tangles and concentrations.

ANNEALING

- Recovery annealing is also accompanied by changes in other properties of cold worked aluminum. Complete recovery from the effects of cold working is obtained only with recrystallization.
- **Recrystallization** is characterized by the gradual formation and appearance of a microscopically resolvable grain structure. The new structure is largely strain-free-there are few if any dislocations within the grains and no concentrations at the grain boundaries.
- **Grain Growth After Recrystallization.** Heating after recrystallization may produce grain coarsening. This can take one of several forms.

Annealing

- Annealing is applied to both grades to promote softening. Complete and partial annealing heat treatments are the only ones used for the non-heat treatable alloys. The exception is the 5000 series alloys which are sometimes given low temperature stabilisation treatment and this is carried out by the producer.
- Annealing is carried out in the range 300-410°C depending on the alloy. Heating times at temperature vary from 0.5 to 3 hours, conditional on the size of the load and the alloy type. Generally, the time need not be longer than that required to stabilise the load at temperature. Rate of cooling after annealing is not critical.
- Where parts have been solution heat-treated a maximum cooling rate of 20°C per hour must be maintained until the temperature is reduced to 290°C. Below this temperature, the rate of cooling is not important.

Solution Heat Treatment

- This is applicable to the heat treatable alloys and involves a heat treatment process whereby the alloying constituents are taken into solution and retained by rapid quenching. Subsequent heat treatment at lower temperatures i.e. ageing or natural ageing at room temperature allows for a controlled precipitation of the constituents thereby achieving increased hardness and strength.
- Time at temperature for solution treatment depends on the type of alloy and the furnace load. Sufficient time must be allowed to take the alloys into solution if optimum properties are to be obtained.
- .

Solution Heat Treatment

- The solution treatment temperature is critical to the success of the procedure. It is desirable that the solution heat treatment is carried out as close as possible to the liquidus temperature in order to obtain maximum solution of the constituents. Accurate furnace temperature and special temperature variation must be controlled to within a range of $\pm 5^{\circ}\text{C}$ for most alloys. Overheating must be avoided i.e. exceeding initial eutectic melting temperatures. Often the early stages of overheating are not apparent but will result in a deterioration of mechanical properties.
- Proper solution heat treatment of the aluminium alloys requires an expert knowledge of the alloy being treated plus the correct heat treatment plant

PRECIPITATION HARDENING

- **General Principles of Precipitation Hardening.** The heat treatable alloys contain amounts of soluble alloying elements that exceed the equilibrium solid solubility limit at room and moderately higher temperatures. The amount present may be less or more than the maximum that is soluble at the eutectic temperature.
- **Nature of Precipitates and Sources of Hardening.** Intensive research during the past forty years has resulted in a progressive accumulation of knowledge concerning the atomic and crystallographic structural changes that occur in supersaturated solid solutions during precipitation and the mechanisms through which the structures form and alter alloy properties. In most precipitation-hardenable systems, a complex sequence of time-dependent and temperature-dependent changes is involved.

PRECIPITATION HARDENING

- **Kinetics of Solution and Precipitation.** The relative rates at which solution and precipitation reactions occur with different solutes depend upon the respective diffusion rates, in addition to solubilities and alloy contents. Bulk diffusion coefficients for several of the commercially important alloying elements in aluminum were determined by various experimental methods.
- **Nucleation.** The formation of zones can occur in an essentially continuous crystal lattice by a process of homogeneous nucleation. Recent investigations provide evidence that a critical vacancy concentration is required for this process and that a nucleation model involving vacancy-solute atom clusters is consistent with certain effects of solution temperature and quenching rate.
- The nucleation of a new phase is greatly influenced by the existence of discontinuities in the lattice. Since in polycrystalline alloys grain boundaries, subgrain boundaries, dislocations, and interphase boundaries are locations of greater disorder and higher energy than the solid-solution matrix, they are preferred sites for nucleation of precipitates.

Quenching

- **Quenching** Quenching is in many ways the most critical step in the sequence of heat treating operations. The objective of quenching is to preserve as nearly intact as possible the solid solution formed at the solution heat treating temperature, by rapidly cooling to some lower temperature, usually near room temperature.
- **Critical Temperature Range.** The fundamentals involved in quenching precipitation-hardenable alloys are based on nucleation theory applied to diffusion-controlled solid state reactions. The effects of temperature on the kinetics of isothermal precipitation depend principally upon degree of supersaturation and rate of diffusion.
- **Quenching Medium.** Water is not only the most widely used quenching medium but also the most effective. It is apparent that in immersion quenching, cooling rates can be reduced by increasing water temperature. Conditions that increase the stability of a vapor film around the part decrease the cooling rate; various additions to water that lower surface tension have the same effect.

Quenching

- The usual quenching medium is water at room temperature. In some circumstances slow quenching is desirable as this improves the resistance to stress corrosion cracking of certain copper-free Al-Zn-Mg alloys.
- Parts of complex shapes such as forgings, castings, impact extrusions and components produced from sheet metal may be quenched at slower quenching rates to improve distortion characteristics.
- Thus a compromise must be considered to achieve a balance of properties in some instances. Quenchants used in slower quenching applications include water heated to 65-80°C, boiling water, aqueous solutions of polyalkalene glycol or forced air blast.

Quenching

- This is a critical operation and must be carried out to precise limits if optimum results are to be obtained. The objective of the quench is to ensure that the dissolved constituents remain in solution down to room temperature.
- The speed of quenching is important and the result can be affected by excessive delay in transferring the work to the quench. The latitude for the delay is dependant on section and varies from 5 to 15 seconds for items of thickness varying from 0.4mm to 12.7mm. Generally, very rapid precipitation of constituents commences at around 450°C for most alloys and the work must not be allowed to fall below this temperature prior to quenching.
- Another factor to be considered in quenching is the work load and the ability of the quenchant to extract the heat at sufficient rate to achieve the desired results.

Age Hardening

- **Aging at Room Temperature (Natural Aging)**
- Most of the heat treatable alloys exhibit age hardening at room temperature after quenching, the rate and extent of such hardening varying from one alloy to another. No discernible microstructural changes accompany the room-temperature aging, since the hardening effects are attributable solely to the formation of zone structure within the solid solution.
- Since the alloys are softer and more ductile immediately after quenching than after aging, straightening or forming operations may be performed more readily in the freshly quenched condition.

Age Hardening

- **Precipitation Heat Treating (Artificial Aging)**
- The effects of precipitation on mechanical properties are greatly accelerated, and usually accentuated, by reheating the quenched material to about 100 to 200°C. The effects are not entirely attributable to a changed reaction rate; as mentioned previously, the structural changes occurring at the elevated temperatures differ in fundamental ways from those occurring at room temperature. These differences are reflected in the mechanical characteristics and some physical properties. A characteristic feature of elevated-temperature aging effects on tensile properties is that the increase in yield strength is more pronounced than the increase in tensile strength. Also ductility, as measured by percentage elongation, decreases. Thus, an alloy in the T6 temper has higher strength but lower ductility than the same alloy in the T4 temper.

Age Hardening

- After solution treatment and quenching, hardening is achieved either at room temperature (natural ageing) or with a precipitation heat treatment (artificial ageing). In some alloys sufficient precipitation occurs in a few days at room temperature to yield stable products with properties that are adequate for many applications. These alloys sometimes are precipitation heat treated to provide increased strength and hardness in wrought and cast alloys. Other alloys with slow precipitation reactions at room temperature are always precipitation heat treated before being used.
- In some alloys, notably those of the 2xxx series, cold working of freshly quenched materials greatly increases its response to later precipitation treatment. Mills take advantage of this phenomenon by applying a controlled amount of rolling (sheet and plate) or stretching (extrusion, bar and plate) to produce higher mechanical properties. However, if the higher properties are used in design, reheat treatment must be avoided.

Age Hardening

- Where natural ageing is carried out the time may vary from around 5 days for the 2xxx series alloys to around 30 days for other alloys. The 6xxx and 7xxx series alloys are considerably less stable at room temperature and continue to exhibit changes in mechanical properties for many years. With some alloys, natural ageing may be suppressed or delayed for several days by refrigeration at -18°C or lower. It is common practice to complete forming, straightening and coining before ageing changes material properties appreciably. Conventional practice allows for refrigeration of alloys 2014 - T4 rivets to maintain good driving characteristics.
- The artificial ageing or precipitation heat treatments are low temperature long time processes. Temperatures range from $115\text{-}200^{\circ}\text{C}$ and times from 5-48 hours. As with solution treatment accurate temperature control and spatial variation temperatures are critical to the process and generally temperatures should be held to a range of $\pm 7^{\circ}\text{C}$.
- The change of time-temperature parameters for precipitation treatment should receive careful consideration. Larger particles or precipitates result from longer times and higher temperatures. The objective is to select the cycle that produces the optimum precipitate size and distribution pattern. Unfortunately, the cycle required to maximise one property, such as tensile strength, is usually different from that required to maximise others such as yield strength and corrosion resistance. Consequently, the cycles used represent compromises that provide the best combination of properties.

- **Precipitation Heat Treating Without Prior Solution Heat Treatment**
- Certain alloys that are relatively insensitive to cooling rate during quenching can be either air cooled or water quenched directly from a final hot working operation. In either condition, these alloys will respond strongly to precipitation heat treatment.
- **Precipitation Heat Treating Cast Products**
- The mechanical properties of permanent mold, sand, and plaster castings of most alloys are greatly improved by solution heat treating, quenching, and precipitation heat treating, using practices analogous to those employed for wrought products.

Fig. 10.22 Detail of [B] in Fig. 10.21. Morphology of the interdendritic fracture. The zones of the retained cohesion in matrix can be observed. 1000×

Fig. 10.23 Morphology of the interdentritic shrinkage on the surface after V-notch impact test at 21 °C (70 °F). Transcrystalline fracture is visible in the eutectic regions. Alloy 356.0 (AlSi7Mg), refined, modified, permanent mold casting. 600×

Fig. 10.24 Morphology of the interdentritic shrinkage on the fracture surface after V-notch impact test at 21 °C (70 °F). In the eutectic regions the transcrystalline fracture is visible. Alloy 356.0 (AlSi7Mg), refined, modified, permanent mold casting. 800×
